SIGNAL-FLOW GRAPHS

Mason's rule

The transfer function $\frac{C(s)}{R(s)}$ of a system represented by a signal-flow graph is

$$\frac{C(s)}{R(s)} = \frac{\sum_k T_k \Delta_k}{\Delta}$$

Where

k = number of forward paths

T_k = the k^{th} forward-path gain

$\Delta = 1 - \sum \text{loop gains} + \sum \text{product of non-touching loop gains taken two at a time} - \sum \text{product of non-touching loop gains taken three at a time} + \sum \text{product of non-touching loop gains taken four at a time} \dots\dots\dots$

$\Delta_k = \Delta - \sum \text{loop gain terms in } \Delta \text{ that touch the } k^{\text{th}} \text{ forward path. } \Delta_k \text{ is formed by eliminating from } \Delta \text{ those loop gains that touch the } k^{\text{th}} \text{ forward path.}$

STABILITY

Routh-Hurwitz criterion

Considering the characteristic equation

$$a_0 s^n + a_1 s^{n-1} + a_2 s^{n-2} + \dots + a_{n-1} s + a_n = 0$$

Form the determinants from the coefficients of the characteristic equation. There are n determinants for n^{th} order system.

The system is stable if and only if the value of each determinant is greater than zero.
